Expansion Bays

The following illustration shows the location of the expansion bays in your server. For installation instructions and information about the types of drives that you can install in these bays, refer to the “Installing Options” chapter in your User’s Handbook.
Removable Media Bays: Your PC Server 704 has four drive bays for removable-media devices, such as tape-backup drives, compact disc-read only memory (CD-ROM) drives, optical drives, or additional diskette drives. One of these drive bays contains an IDE CD-ROM drive, which comes standard in all PC Server 704 models. For information about inserting CDs and using the CD-ROM drive, refer to your User's Handbook.

Diskette Drive Bay: This dedicated bay contains a 3.5-inch, 1.44 MB diskette drive, which comes standard in all PC Server 704 models. This drive uses 1 MB and 2 MB diskettes (MB equals approximately 1,000,000 bytes). For optimum use, format 1 MB diskettes to 720 KB and format 2 MB diskettes to 1.44 MB.

Hot-Swap Bays: The hot-swap bays support up to 12 SCSI hard disk drives. The number of preinstalled drives and their capacities vary by model. The hot-swap feature enables you to remove and replace hard disk drives without turning off the server.
Expansion Slots and Input/Output Ports

The following illustration shows the expansion slots and the input/output connectors (ports) on the rear of the server.
Keyboard Connector: The cable from your keyboard connects here.

Mouse Connector: This is where the mouse cable connects to the server. This port sometimes is called an auxiliary-device or pointing-device port.

Serial Connectors: Your server has two, 9-pin serial connectors (COM1 and COM2). The serial signal cable for a modem or other serial device usually connects here. If you are using a 25-pin signal cable, you need a 9-pin-to-25-pin adapter cable.

Parallel Connector: This is where the signal cable for a parallel printer or other parallel device connects to your server.

Video Connector: The monitor signal cable attaches to this 15-pin connector.

Expansion Slots: The PC Server 704 has four extended industry standard architecture (EISA) expansion slots and six peripheral component interconnect (PCI) expansion slots. You can install PCI or EISA adapters to provide communication, specialized graphics, and sound. Many adapters provide bus-master capabilities, which enable the adapters to perform operations without interrupting the system microprocessors.

External SCSI Connector Knockouts: An optional external SCSI cable can be attached to an internal SCSI connector by using one of these knockouts.

Power Connectors: The system power cords connect here. Your PC Server 704 supports up to three hot-swap power supplies.
Padlock Loops and Power Supplies
The following illustration shows the location of the padlock loops and hot-swap power supplies on your PC Server 704.
**Padlock Loops:** The two side cover padlock loops enable you to insert padlocks (not provided) to secure the top and side covers to the system unit. The electromagnetic interference (EMI) panel on the front of the server also has a padlock loop. You can insert a small padlock (not included) through this loop to secure the EMI panel to the system unit and help prevent unauthorized access to the hard disk drives in the hot-swap bays.

**Hot-Swap Power Supplies:** All PC Server 704 models support three 420 watt hot-swap power supplies. Power is drawn equally from all installed supplies. In a three-supply system, the third power supply provides redundant power. An isolating device on each power supply is designed to ensure that a failure of one supply does not affect the operation of the remaining functional supplies. And, if one of the power supplies fails in a three-supply system, the third (redundant) supply takes over immediately, so there should be no interruption to your server's availability or performance.

*Note:* Not all PC Server 704 models support hot-swap power supplies. You can identify a hot-swap supply by the HS on its label. If you are working with multiple models of the PC Server 704, be sure to check the power supply label before you attempt to hot-swap a power supply.

**Power-Good Light and Current-Good Light:** These lights provide status information about the power supply as follows:

International Capabilities

As always, your IBM server meets stringent world wide certifications for power, electromagnetic compatibility (EMC), and safety. It is suitable for use worldwide. The voltage-sensing feature allows the server to automatically set itself to match differing power sources, because electric power can vary from country to country.

Language is another factor to consider. English is the default setting for the basic input/output system (BIOS) messages, but you can select a different language to display using the built-in Setup program. Your server also can use special editions of operating systems that let the system and keyboard operate in a variety of languages.
Operating-System Support

You can use your server in a variety of environments to do many different tasks. To meet the requirements of these environments, your server supports several operating systems. Some of these operating systems support the high-performance, symmetric multiprocessing (SMP) capability of your server.

For the latest information about the operating systems supported by your PC Server 704:

- In the U.S. and Puerto Rico, call 1-800-772-2227.
- In Canada, call 1-800-565-3344.

In all other countries, contact the IBM support organization that services your area, your IBM marketing representative, or your IBM authorized reseller.

IBM and other manufacturers of operating systems, network programs, and application programs periodically make software updates available. These updates provide enhancements and corrections for the off-the-shelf versions of the software. To ensure that the software you install on your server functions properly, contact the manufacturers of the software that you intend to install and obtain the most current software updates.

If you intend to install an IBM operating system or network program, such as OS/2 for SMP or OS/2 LAN Server, you can obtain the most current software updates from the IBM Personal Software Solutions Center. These software updates are called ServicePaks or corrective-service diskettes (CSDs). In the U.S., you can call the IBM Personal Software Solutions Center at 1-800-992-4777.
Reliability, Availability, and Serviceability

Chapter 2. Server Performance

Your productivity and satisfaction, as well as the productivity and satisfaction of everyone on your network, depends on server performance. Many factors can influence this performance, including the configuration of the hardware, application workloads, operating-system configuration parameters, and the server operating environment.

The information in this chapter can help you avoid potential performance bottlenecks, and includes suggestions to help you maximize the performance of your server.

Understanding Server Performance
You can optimize the performance of your server by balancing the performance of its main components. These include:

- Network and application programs
- Network adapter
- System memory
- System microprocessor
- Hard disk subsystem (UltraSCSI controllers and drives)

Network and Application Programs
Most complex programs allow you to change specific parameters to improve performance in a network environment. Always check the documentation that comes with your software to determine which parameters affect performance, and which parameters you can change to increase performance.

The original parameter settings provided by network programs usually support a network with 12 to 18 concurrent users. If you have a larger network, or increase the size of a network, you will probably need to adjust some of these settings to maintain adequate performance.

Make sure that you record the original settings before you make any changes. In the unlikely event that performance decreases, you can change the settings back to their original values. Also document changes by making remarks, such as the date and reason for the changes, above or below the values that you change. This
information can save you valuable time if you need to make additional adjustments.

**Network Adapter**

Several network adapters are available for your PC Server 704. PCI bus-master network adapters are best suited for use in network servers. The primary value of using a bus-master network adapter is added capacity or, in the case of a heavily loaded server, improved performance.

In addition, PCI bus-master network adapters provide a higher throughput rate, because they handle most of the network processing and leave the system microprocessor free for other tasks. When you use a bus-master network adapter, the network throughput is less dependent on the type of system microprocessor and more dependent on the network adapter design and the network software.

Adding a faster network adapter provides additional throughput. The total number of transactions that the server processes per second increases, and the application response time decreases. However, keep in mind that this reduction in response time is limited. As you add more users, the effects of the faster network adapter are offset by the increase in data-space access and write-data processing (which reduces the disk-cache-hit rate and overall server performance). See “Cache Memory” on page 34 for more information.

**System Memory**

When you have a large network or you increase the size of a small network, you might need to install additional memory to maintain adequate performance. This additional memory might be needed to support additional application programs, buffers, or control blocks.

The PC Server 704 supports up to 2 GB of system memory. Your server comes with a minimum of 256 MB of system memory. You can install additional 60 ns parity memory modules in the 16 sockets on the memory board.
System Microprocessor

One way to optimize the performance of your server is to install an additional microprocessor. The PC Server 704 comes with two processor boards, and each processor board supports up to two Pentium Pro microprocessors. Each Pentium Pro microprocessor has global access to all I/O devices and has an integrated:

- Level-1 cache, 16 KB
- Level-2 cache, 512 KB
- Cache controller
- Advanced programmable interrupt controller (APIC)

Integrating the level-2 cache, cache controller, and APIC into the Pentium Pro microprocessor improves performance and alleviates some of the performance bottlenecks experienced with earlier microprocessor designs. See “Microprocessor Performance” on page 27 for more information.

Another way to improve system microprocessor performance is to lighten its load by using bus masters. Bus masters can handle tasks, such as network processing or data transfers, and provide relief for an overloaded system microprocessor. See “Bus Master Implementation” on page 40 for more information.

Hard Disk Subsystem

Two UltraSCSI PCI bus-master controllers come standard in all PC Server 704 models. These bus-master controllers significantly increase performance by handling the processing of SCSI commands and data transfers, leaving the system microprocessors free to handle other tasks.

You can install up to 12 hot-swap hard disk drives to increase disk storage and performance. Your User’s Handbook contains instructions for installing and configuring additional drives.

Some PC Server 704 models come with a redundant array of independent disks (RAID) adapter preinstalled as a standard feature. This PCI RAID adapter enables you to configure RAID levels 0, 1, and 5 disk arrays.
Disk arrays use multiple hard disk drives to provide faster input and output rates than a single large-capacity drive. Because the files are stored on individually addressable disks, they can be found more quickly during read requests. As always, the amount of performance improvement depends on the application programs that you run on the server and the type of array that you configure. See Chapter 7, “Disk Arrays” on page 55 and your RAID adapter documentation for more information.

**Estimating Server Performance and Capacity**

There is no simple method of evaluating your server performance for all environments. The hardware, software, applications, workloads, and number of users all affect server performance.

When you are ready to do a performance evaluation, use a systematic approach, such as the following:

- Define the functional requirements of the server for your working environment.
- Define what you consider to be adequate performance, such as response times, transaction rates, and number of users.
- Understand what factors affect server performance.
- Decide what an approximate configuration of applications for your work environment would be.
- Measure the current performance of your server using a variety of application configurations. Use the performance results to locate bottlenecks and to determine which configuration provides sufficient performance today and allows room for growth.
- Ensure that the performance of the server will remain acceptable if one of the components fails.
Improving Server Performance

Before you begin to experiment with applying upgrades or enhancements to improve performance, remember that the subsystem that causes a bottleneck depends largely on the applications you are using.

Try to determine which subsystem is the most likely bottleneck for your environment, then concentrate on obtaining improvements for components within that subsystem. Some changes might improve the performance of one application, but degrade the performance for other applications. If this occurs, you will need to assess the trade-offs.

Once you understand the factors that affect server performance, you can use a methodical approach to improving it. A good example of this type of approach is:

1. Measure the current server performance.
2. Identify the performance bottlenecks.
3. Upgrade components that cause the bottlenecks.
4. Measure the new performance of the server.

For example, if the bottleneck is memory, you could install additional memory; if it’s the microprocessor, you could install an additional microprocessor; if it’s the hard disk subsystem, you could install additional hard disk drives or create a disk array. You can replace slow network adapters with faster ones, or you can install additional adapters, and so on.
Chapter 3. Microprocessors and Memory

The processing center of your server contains devices that run programs and store data used by programs. These devices include the microprocessor and the components of the memory subsystem.

Microprocessor

The microprocessor is an integrated circuit that performs most of the control and computing functions of your server. Your server contains two processor boards, and each processor board can support two Pentium Pro microprocessors. You can install up to three more microprocessors in your server. Additional microprocessors enhance performance and provide symmetric multiprocessing (SMP) capability.

Microprocessor Clock

The rate at which the microprocessor performs its basic operations is called the clock speed. Examples of basic operations include fetching an instruction from memory, decoding it, executing it, writing the result to memory, and so on. The process of executing an instruction always consists of several basic operations. The design of the microprocessor determines the maximum clock speed at which it can operate reliably, and the design of the server determines the optimal clock speed for the server. Clock speed is measured in megahertz (MHz). A clock cycle is the time unit that measures how long the microprocessor takes to perform a basic operation at a given clock speed. Clock cycles are measured in nanoseconds (ns) and are inversely related to the clock speed. For example, at a clock speed of 25 MHz, one clock cycle takes 40 ns; at a clock speed of 100 MHz, one clock cycle takes 10 ns. The microprocessor in your server operates at two different clock speeds: one speed for transferring data into and out of the microprocessor and a faster speed for operations within the microprocessor.

Microprocessor Performance

The Pentium Pro microprocessor gains its high performance through its innovative design. Dynamic execution is the term given to the micro-architecture design of the Pentium Pro microprocessor. This dynamic design enables the Pentium Pro microprocessor to speculatively execute instructions in any order, but always complete
the instructions in their original program order. Looking 20 to 30 instructions ahead of the instruction pointer, the Pentium Pro microprocessor predicts program flow, and then analyzes the program data flow to determine the best order in which to execute the program’s instructions. This approach eliminates the constraint for linear instruction sequencing and enables the microprocessor to schedule up to five instructions per clock cycle; although, a sustained rate of three instructions per clock cycle is more typical.

One of the design features that helps the Pentium Pro achieve its higher clock rate is its pipeline implementation. In a pipeline, multiple instructions are in various stages of execution. For example, while one instruction is fetched, two are decoded, another is executed, and the results of another are written to memory. This parallelism speeds up instruction execution significantly when compared to a microprocessor that is running at the same speed, but does not use pipelining. The Pentium Pro microprocessor has a 12-stage, superpipelined implementation. This superpipelined implementation trades less work per pipestage for more stages, which results in a pipestage time that is 33 percent less than the pipestage time of a standard Pentium microprocessor.

Another design feature that enables the Pentium Pro to achieve its higher clock rate is the integration of several system components. Each Pentium Pro microprocessor in your server contains a 512 KB level-2 cache, a cache controller, and an advanced programmable interrupt controller (APIC). In earlier personal computers, these system components were not contained within the microprocessor. Instead, they were separate components on the system board, processor board, or memory board. This added level of integration improves performance by alleviating some of the performance bottlenecks experienced with earlier system designs. This integration also results in a microprocessor bus that more closely resembles a symmetric multiprocessing (SMP) system bus rather than resembling a previous generation processor-to-cache bus.

**Microprocessor Registers and Interfaces**

The microprocessor needs data or instructions, or both, for each basic operation. Instructions and data are copied from memory into data-storage locations known as registers, in the microprocessor. The
The microprocessor can read from and write to its registers very quickly. Registers also store the results of processing operations until the results are needed for other operations or are written to memory.

The microprocessor data interface is the connection between the microprocessor and the data bus. The width of the data bus determines which type of adapters (16-bit or 32-bit) the server supports. Your server has a 32-bit data bus, and it uses a microprocessor that has a 64-bit data interface that supports both 16-bit and 32-bit adapters.

The set of instructions that the microprocessor can perform determines whether a particular program will run in the server. Programs written for a 32-bit interface require only that the microprocessor be capable of decoding and performing 32-bit instructions. The width of the data bus does not affect software compatibility.

The size of the microprocessor address interface, which is the connection between the microprocessor and the address bus, determines the width of the address bus and the amount of physical memory the microprocessor can address. The Pentium Pro microprocessor in your server can address up to 4 GB of physical memory. Physical memory is described in “Physical Memory and Virtual Memory” on page 33.

Real Mode and Protected Mode
The microprocessor has a real mode with a 1 MB address space. The real mode is the default condition for the microprocessor; the microprocessor is always in the real mode after the server is turned on and before any operating system is started. The real mode does not support virtual memory (see “Physical Memory and Virtual Memory” on page 33).

The microprocessor also has a protected mode that supports virtual memory and allows the microprocessor to address more than 1 MB of memory. In protected mode in a multitasking environment, the microprocessor manages the memory so that each program is protected from interference from other programs running at the same time.
The operating system you install determines whether the microprocessor stays in the real mode or is switched to the protected mode. For example, when the server runs DOS, the microprocessor stays in the real mode. DOS makes only limited use of the capabilities provided by the protected mode. When the IBM Operating System/2 (OS/2) starts, it switches the microprocessor to the protected mode. The OS/2 operating system uses the virtual memory and multitasking capabilities provided by the protected mode of the microprocessor.

Note: The OS/2 operating system has a real mode and a protected mode. These operating-system modes are not related to the real mode and protected mode of the microprocessor.

Numeric Computing
The microprocessor in your server has an execution unit that performs only floating-point arithmetic and mathematical instructions. This execution unit, called the floating-point unit (FPU), executes the types of instructions previously executed by the separate math coprocessors used in earlier personal computers. These instructions, generally called numeric instructions, perform basic floating-point arithmetic and a variety of mathematical functions.

The control circuits within the microprocessor pass data and instructions to the FPU, which then performs the mathematical operations. Other units, such as the integer units, can execute instructions concurrently with the FPU. The FPU is pipelined, so several floating-point instructions can be in various stages of execution simultaneously.

Programs that require extensive mathematical calculations run much faster when the FPU performs the calculations, because the FPU is designed specifically for that purpose. A program that is intended to use the FPU must contain specific instructions that are recognized by the microprocessor. Otherwise, the microprocessor will not assign the operation to the FPU, and the integer units will perform the calculations.
Memory Subsystem

The memory subsystem consists of random access memory and read-only memory, physical memory and virtual memory, and cache memory.

Memory Controller

The memory controller is a device on the system board that controls access to system memory by the microprocessor and I/O devices. Registers in the memory controller contain information about the amount and type of memory that is installed in the server. During a system reset, the POST routine writes this information into the registers.

A 32-bit direct-memory-access (DMA) controller is integrated onto the system board in your PC Server 704. This DMA controller is a bus master that manages all DMA data transfers between system memory and I/O devices. See “Bus Master Implementation” on page 40 for more information.

Direct Memory Access

Direct memory access is a method used to transfer large amounts of data between system memory and I/O devices without the assistance of the microprocessor. DMA is more efficient than programmed I/O, in which the microprocessor reads the data from the sending device, and then writes it to the receiving device. In DMA data transfers, data can bypass the system microprocessor as it moves between system memory and I/O devices. DMA improves server performance because the microprocessor does not have to interrupt its processing activities to manage data transfers.

Transferring data between system memory and an I/O device requires two steps. First, the microprocessor gives the DMA controller the location, destination, and amount of data that is to be transferred. Then the DMA controller transfers the data, allowing the microprocessor to continue with other processing tasks.

When a device needs to use the bus to send or receive data, it competes with all the other devices that are trying to gain control of the bus, in a process known as arbitration. The DMA controller does
not arbitrate for control of the bus; instead, the I/O device that is sending or receiving data (the DMA subordinate) participates in arbitration. The DMA controller takes control of the bus when the central-arbitration-control point grants the request of the DMA subordinate. For more information about bus masters, subordinates, and arbitration, see “Bus Master Implementation” on page 40.

The functions of the memory controller vary and can include memory interleaving, which is a method of reducing the time the microprocessor has to wait for system memory to respond during memory I/O operations.

Memory Interleaving
In servers that use noninterleaved memory, the speed of memory I/O operations is limited by the speed at which system memory can respond. The speed of a memory I/O operation is measured in microprocessor clock cycles. Therefore, the microprocessor clock speed determines the minimum time required for a memory I/O operation.

The microprocessors in your server are so fast that system memory cannot respond to read and write requests as quickly as the microprocessor can send them. To reduce the time that the microprocessor spends waiting for system memory to respond, your server supports two- and four-way interleaved memory.

Random Access Memory and Read-Only Memory
Random access memory (RAM) is used for temporary storage of data and instructions during processing. RAM is contained in memory components known as single inline memory modules (SIMMs). It is volatile memory, which means that to retain its contents, it must be constantly refreshed by an electrical current. While the server is turned off, no current is supplied to the single inline memory modules, so no data is retained in RAM.

Your server supports up to 2 GB of 60 ns parity memory. You can add memory to your server by installing matched sets of 60 ns parity memory modules in the 16 connectors on the memory board.
In addition to volatile RAM, the system board has a small area of nonvolatile RAM (NVRAM). Using a small current from the system battery, NVRAM retains its contents while the server is turned off. Your passwords, the time and date, and the system configuration information are stored in NVRAM.

Read-only memory (ROM) is used for storage of programs that the server uses for startup procedures and other internal operations. These programs are permanently encoded in the ROM module. ROM is nonvolatile memory, and retains its contents when the server is turned off.

Generally, the contents of a ROM module cannot be modified. However, the type of ROM modules in your server can be reprogrammed. Electrically erasable programmable ROM (EEPROM) modules (or flash memory) can be reprogrammed while they are in the server. For example, the POST and BIOS code in your server is stored in flash memory so that it can be updated whenever enhancements are made.

Physical Memory and Virtual Memory

Physical memory consists of all the writable memory locations in the server, most of which are in single inline memory modules. Portions of the physical memory are reserved for the operating system, for the power-on self-test, and for the video data that is being displayed. The part of physical memory available for instructions and data that the server uses to run programs is system memory.

Virtual memory is memory that appears to be allocated to application programs. The operating system uses a portion of the hard disk as virtual memory, swapping data and instructions between the hard disk and physical memory. The portion of the hard disk used for virtual memory is often called swap space. The amount of swap space on the disk determines the amount of available virtual memory, which is typically much larger than the actual amount of installed physical memory.

Virtual memory supports very large programs and multitasking. In multitasking, multiple programs run simultaneously. The memory...
requirements of these programs can exceed the amount of available physical memory. The operating system allocates the memory required by each program as virtual memory and manages the physical memory, swapping portions of each program's address space to the hard disk as required.

The maximum amount of physical memory that you can install in your server, and the maximum amount of virtual memory that the operating system can allocate, are determined by the microprocessor.

The width of the microprocessor address interface limits the amount of physical and virtual memory that the microprocessor can address. The microprocessor in your server can address a maximum of 4 GB of physical memory and 64 TB (TB equals approximately 1,000,000,000,000 bytes) of virtual memory in the protected mode.

Cache Memory

Cache memory is high-speed memory, known as static random access memory (SRAM), that can respond to memory operations without imposing wait states on the microprocessor. A wait state is a period of time (one microprocessor clock cycle) during which the microprocessor suspends processing and waits for system memory to respond to a read or write operation. Wait states cause the server to operate less efficiently than it would if the microprocessor were able to continue processing data during read or write operations.

To reduce the time that the microprocessor spends waiting for system memory to respond, your server uses cache memory. Cache memory improves server performance by temporarily storing frequently used data and instructions in a cache, a small buffer between the microprocessor and system memory.

Each Pentium Pro microprocessor in your server contains a cache controller, level-1 cache, and level-2 cache. Cache performance depends on the size of the cache and the application programs you are running on your server.
Level-1 Cache

The level-1 cache, which is part of the microprocessor, consists of very fast RAM. This type of cache memory is also referred to as internal cache. The Pentium Pro microprocessor contains 16 KB (KB equals approximately 1000 bytes) of internal level-1 cache.

The level-1 cache stores the data and instructions most frequently used by the microprocessor in the current execution context. (The execution context is the executable code and associated data used by the program running on the microprocessor.) Because the microprocessor sends many fewer read and write requests to system memory, a level-1 cache enables a microprocessor to execute programs much faster than if it had to access system memory for each request. When the execution context changes, the cache controller copies new data and instructions into the level-1 cache, replacing data and instructions that are no longer needed.

Server performance improves each time the microprocessor finds what it needs in the cache (a cache hit). The microprocessor is designed so that the cache hit rate is very high, and a penalty for a cache miss is minimized. A cache miss occurs when the information needed by the microprocessor is not available in the cache. In the case of a cache miss, the integrated cache controller quickly locates the information needed in the level-2 cache or system memory, and then copies the information into the level-1 cache. The cache controller manages the use of the cache so that the number of cache hits far exceeds the number of cache misses.

Level-2 Cache

Each Pentium Pro microprocessor in your server also contains 512 KB of level-2 cache. The level-2 cache provides an intermediate level of storage between level-1 cache and system memory. Although level-2 cache accesses are slower than level-1 cache accesses, level-2 cache accesses are still much faster than system memory accesses.

In the case of a level-1 cache miss, the microprocessor can access the level-2 cache relatively quickly. If the microprocessor does not find what it needs in the level-2 cache (a second-level cache miss), the cache
controller locates the data or instruction in system memory; then copies it into one of the caches.

**Write-Back and Write-Through Modes**

For maximum performance, your PC Server 704 caches are set to the write-back mode. In the write-back mode, the microprocessor updates the cache, and then the cache controller updates system memory. While the cache controller is updating system memory, which is a relatively lengthy process, the microprocessor is free to perform other operations.

You can use the built-in Setup program to change the cache settings to the write-through mode. The write-through mode, however, is not recommended because it provides substantially reduced performance. In the write-through mode, the microprocessor updates the caches, and then updates system memory. Because the microprocessor must write directly to system memory, which runs about five times slower than the cache, performance is substantially reduced.
A bus is an electrical pathway for transferring signals and power among microprocessors, memory, adapters, and I/O devices. The signals include addresses, data, and control information.

The PC Server 704 incorporates two bus-architecture designs: the extended industry standard architecture (EISA), which supports PC compatibility and a wide range of adapters; and the peripheral component interconnect (PCI), which provides a high-throughput local bus.

You can install a variety of EISA, ISA Plug-and-Play, and PCI adapters in the expansion slots on the system board. These expansion slots provide paths for transferring data to and from the adapters.

The System Configuration Utility is PCI and Plug-and-Play aware, and it complies with the EISA Specification (version 3.12) and the ISA Plug-and-Play Specification (version 1.1).

### EISA Bus Overview

The PC Server 704 EISA bus provides:

- Memory addressing, 32-bit
- Type A transfers at 5.33 MBps
- Type B transfers at 8 MBps
- Burst-mode transfers at 33 MBps
- Data transfers of 8-, 16-, or 32-bits
- Interrupt sharing
- Automatic translation of bus cycles between EISA and ISA masters

One of the benefits of EISA is that it allows you to install and use both EISA and ISA adapters and the devices that they support. Because EISA is fully backward compatible, you can install both old and new ISA adapters and software in your server.

The System Configuration Utility (SCU) programs, supplied with your server, automatically detect and configure EISA adapters. However, with some older ISA adapters, you might need to set...
switches or jumpers. The SCU programs will help you determine the necessary switch and jumper settings.

**PCI Bus Overview**

The PCI bus is a 32-bit local bus that provides a high-speed data path between the processor boards and peripheral devices, such as the video and hard disk subsystems. The implementation of this industry-standard bus in your server supports PCI bus speeds up to 33 MHz, and allows PCI masters direct access to system memory.

You can install PCI adapters in the six, 32-bit PCI expansion slots on the PC Server 704 system board. Your PC Server 704 has two independent PCI buses. Each bus provides three, 32-bit PCI expansion slots.

The first PCI bus operates at 33 MHz and connects the microprocessor bus to the PCI-to-EISA bridge card, and three PCI expansion slots. The second PCI bus connects the microprocessor bus to the integrated UltraSCSI controllers and three PCI expansion slots.

The PC Server 704 PCI bus architecture provides support for:

- Memory addressing, 32- and 64-bit
- Burst transfers at 133 MBps
- Data transfers of 8-, 16-, and 32-bits
- Plug-and-Play peripherals
- Interrupt control
- Arbitration for six PCI masters
- General purpose I/O ports
- Keyboard emulation
- The front-panel interface and LCD
- Security features (such as system board temperatures and intrusion-detection switches)

**Bus Parity Checking**

The PCI bus supports *bus parity checking*, which is a method of verifying that data was not changed during a data-transfer operation. Bus parity checking uses an extra bit, known as a *parity*
bit, that is sent with each byte of data as it is transferred across the bus. The parity bit is set to 1 or 0 so that each byte has an odd number of 1's (if the server uses odd parity) or an even number of 1's (if the server uses even parity). If the parity (odd or even) of the received byte does not match the parity of the byte as it was sent, an error occurred during transmission and the receiving device can request the sending device to send the data again.

Bus parity checking is a common feature in servers. It is not 100% accurate, but it greatly reduces the chance for errors. It is essential for most operations because of fast I/O devices, complex I/O configurations, and large memory subsystems.

**EISA and PCI Shared Features**

The EISA and PCI implementations in your PC Server 704 share some fundamental features. Your server automatically configures adapters for both buses. The System Configuration Utility (SCU) programs can automatically assign interrupt levels, I/O addresses, memory addresses, arbitration levels, and other system resources to the adapters in your server.

Both buses are implemented as 32-bit buses. Both have 32 signal paths for data; 32 bits of address or data can be sent across each bus simultaneously.

Both buses support burst data transfers; an address and multiple data words (each containing 32 bits) can be sent in each transfer. The address specifies the location of the data to be sent; a bus command specifies the number of data words to send.

Each bus supports data transfers from only one device at a time. A bus arbitration mechanism determines which device can access the bus at a given time.

Both buses have several functions. In your server, each bus is used as an expansion bus, an address bus, and a data bus.
Expansion Bus
An expansion bus supports the addition of adapters to add new functions to your server. Adapters plug into connectors, called expansion slots, on the system board.

The EISA expansion bus provides four connectors for adapters; the PCI expansion bus provides six connectors. These connectors provide paths for transferring data to and from the adapters.

Address and Data Bus
When a device sends data, it identifies where the data is stored (source) and where it is to be sent (destination). Each location is identified by a unique number, known as an address. Each memory location and I/O device that is attached to a bus has an address. The sending device uses the bus as an address bus to send the target address to the receiving device. Then the sending device uses the bus as a data bus to send the data.

The width of a bus determines the size of the address space available to the bus. The EISA bus and the PCI bus both have a 32-bit address bus, enabling devices on the bus to address up to 2 GB of memory.

The width of the data bus determines how much data can transfer simultaneously. Both the EISA bus and the PCI bus in your server provides a 32-bit data path. However, the full width of the 32-bit data bus is used only when both the sending device and the receiving device are 32 bits wide.

Bus Master Implementation
A bus master is a device or an adapter that can take control of (own) the bus. The system microprocessor is the first owner of the bus at system startup. Other bus masters receive ownership of the bus by halting the system microprocessor. All four of the EISA expansion slots support bus-master adapters. The PCI bus provides bus-master support for six masters.

A bus master can have its own microprocessor, instruction cache, and memory. By taking over some of the work of the system
microprocessor, bus masters create a multiprocessing environment and increase overall system performance.

Typical bus masters include:

- Memory and cache controllers
- Disk controllers
- DMA controllers
- Video controllers and adapters
- Network interface adapters

Once a bus master has control of the bus, it can issue bus commands to other devices on the bus. The target of a bus master, called a subordinate, executes bus commands issued by a bus master. Subordinates can initiate service requests, such as interrupts, but subordinates never own the bus.

A bus master can also be a subordinate, but, at a given time, it must be either a bus master or a subordinate. It cannot be both simultaneously.

**Bus Arbitration**

The EISA and PCI bus architectures support arbitration, a process that determines which of two or more competing devices has control of the bus at any given time.

When multiple devices need to own a bus at the same time, these devices participate in arbitration. Every device that can arbitrate for control of the bus is assigned a priority level, known as an arbitration level, that is used to determine which device should control the bus next.

EISA masters arbitrate for control of the bus based on the expansion slot in which they reside. The sequence is as follows: 1, 2, 3, 4, 1, 2, 3, 4, and so on. This is because slots 1 and 2 and slots 3 and 4 share arbitration requests. The arbitration level for each PCI master is contained in a software file.

Both buses have fairness features to ensure that all devices get a turn to own the bus, even those having low priority levels. The fairness
feature guarantees that none of the devices are locked out of the bus and that each device can gain control of the bus within a given amount of time. When you configure your server, you can disable the fairness feature for a device so that it controls the bus more than other devices. However, if you disable the fairness feature for a device, that device can monopolize the bus. Disabling the fairness feature for more than one device is risky. You could cause some devices for which the fairness feature is enabled to be completely locked out of the bus, including the microprocessor. Therefore, it is best to leave the fairness feature enabled for all devices.
Chapter 5. Data Storage Devices

IBM data storage devices are available for use with your server. You can use these storage devices to expand the data storage capacity of your server.

**Hard Disk Subsystem**

All IBM PC Server 704 models come with two bus-master UltraSCSI controllers on the system board. These controllers enable the system to communicate with devices, such as hard disk drives, CD-ROM drives, tape drives, scanners, and printers. For more information about these controllers, see Chapter 6, “SCSI Subsystem” on page 49.

Some PC Server 704 models come with a PCI RAID adapter preinstalled as a standard feature. If your server is a non-disk-array model, you can install a PCI RAID adapter and hard-disk drives to create a disk-array subsystem. See Chapter 7, “Disk Arrays” on page 55 for more information.

The hot-swap capability for hard disk drive replacement, provided in all PC Server 704 models, enables you to correct failures without turning off the server.
**Internal Bays**

Your server comes with one 3.5-inch, 1.44 MB diskette drive and one IDE CD-ROM drive. The number of hard disk drives installed varies by model.
Removable Media Bays: Your PC Server 704 has four drive bays for removable-media devices such as tape-backup drives, compact disc-read only memory (CD-ROM) drives, optical drives, or additional diskette drives. One of these drive bays contains an IDE CD-ROM drive, which comes standard in all PC Server 704 models. For information about inserting CDs and using the CD-ROM drive, refer to your User’s Handbook.

Diskette Drive Bay: This dedicated bay contains a 3.5-inch, 1.44 MB diskette drive, which comes standard in all PC Server 704 models. This drive uses 1 MB and 2 MB diskettes. For optimum use, format 1 MB diskettes to 720 KB and format 2 MB diskettes to 1.44 MB.

Hot-Swap Bays: These drive bays support up to 12 SCSI hard disk drives. The number of preinstalled drives and their capacities vary by model. The hot-swap feature enables you to remove and replace hard disk drives without turning off the server.
Direct Access Storage Devices

In a direct access storage device (DASD), the time required to access data is not dependent on the location of the data on the storage medium. Direct access storage devices include diskette drives, hard disk drives, CD-ROM drives, and rewritable optical drives. All of these devices, except hard disk drives, are removable-media drives.

SCSI Hard Disk Drives

The two UltraSCSI controllers on the system board each support up to 15 SCSI devices, including hard disk drives, CD-ROM drives, rewritable optical drives, and tape drives.

The PCI RAID adapter, that comes preinstalled as a standard feature in disk-array models, has three independent channels. Each channel supports up to 15 SCSI devices.

For a current list of the SCSI hard disk drives available for your PC Server 704, contact your IBM marketing representative or your IBM authorized reseller.

CD-ROM Drive

The *compact disc-read only memory* (CD-ROM) drive uses a compact disc (CD) that the server can read from but not write to. You can view the data, but you cannot change or update the data.

All IBM CD-ROM drives use industry-standard 5.25-inch CDs with a capacity of approximately 650 MB of data. Diskette drives, hard disk drives, and tape drives use a magnetic recording technique. However, CD-ROM drives use an optical technique that records and reads data at a much higher density than magnetic recording can achieve.

The IDE CD-ROM drive installed in your server supports CD-ROM Extended Architecture (XA), which is a standard for interleaving different types of data such as video, audio, and text. This enables your server to support advanced multimedia applications. Your CD-ROM drive also supports the Kodak Photo CD standard for recording pictures on CDs.
Handle a CD by the edges only. Periodically clean your CDs by wiping them with a soft, lint-free cloth, from the center of the CD to the outer edge. Do not clean CDs in a circular pattern, because this can cause loss of data.

**Tape Drives**

Backing up the entire contents of a hard disk to diskettes can be very time-consuming and, in the case of a network server with multiple hard disks, can require hundreds of diskettes. A faster and more efficient way to back up the data is to use a tape-backup drive.

Tape drives provide a cost-effective way to back up your files. You can copy several billion bytes of data from the hard disks to a single tape. Data is stored in the same sequence as it was entered.

The IBM 24/48 GB Internal Tape Autoloader is available for use with your server.

**The IBM 24/48 GB Internal Tape Autoloader**

You can install this autoloading tape-backup drive in one of the removable-media drive bays. This drive has six cartridges that can each store up to 8 GB of data. In the native mode, this drive supports a data-transfer rate of 510 KBps, but this data-transfer rate doubles when the data-compression feature is used. This drive also supports burst-data transfers of 3 MBps in the asynchronous mode and 7.5 MBps in the synchronous mode. A convenient feature of this tape-backup drive is its ability to perform up to 8 GB of backup every six days completely unattended.
The small computer system interface (SCSI) enables the system to communicate with devices such as hard disk drives, CD-ROM drives, tape drives, scanners, and printers.

All IBM PC Server 704 models come with two bus-master UltraSCSI controllers on the system board. Disk-array models also come with a PCI RAID adapter preinstalled as a standard feature.

These UltraSCSI controllers support:

- A variety of devices that conform to ANSI SCSI Standards:
  - X3.131-1986 (SCSI)
  - X3.131-1994 (SCSI-2)
  - X3.253-1995 (SCSI-3 parallel-interface)
  - X3.277-1996 (SCSI-3 Fast-20 parallel-interface)

- Devices compatible with the SCSI Common Command Set.

- Removing and replacing hard disk drives without turning off the server (hot-swapping).

- Multiple physical devices.

  The two UltraSCSI bus-master controllers on the system board each support a maximum of 15, 8-bit or 16-bit physical SCSI devices. The 16-bit devices support SCSI IDs 0 to 15, while 8-bit devices support only IDs 0 to 7. See your SCSI Software User’s Guide for more information.

  The PCI RAID adapter, that comes preinstalled as a standard feature in disk-array models, has three independent channels. Each channel supports up to 15 SCSI devices.

- Functions unique to a particular SCSI device (when the device manufacturer provides the appropriate device driver that supports the unique function).

**Advantages of the SCSI Subsystem**

The SCSI standards define the interface through which the system communicates with different types of devices. Before the SCSI standards were developed, most physical devices required their own controllers (usually adapters). These adapters could support only
one device or multiple devices of the same type. Because each device required support from the system microprocessor, every device added to the system increased the workload on the microprocessor. Also, because almost every device required its own adapter in a separate expansion slot, flexibility and growth were limited by the number of expansion slots in the system.

The SCSI subsystem produces significant improvements in system performance and flexibility over other I/O interfaces. Each SCSI device has a built-in device controller that interprets the SCSI command set. The SCSI standards define the commands and messages used in the interface.

Several devices can operate concurrently and share the interface. This means significantly higher data-transfer rates and faster, more efficient, I/O management for network servers. The SCSI controller is the key component in the SCSI subsystem. You can connect internal and external physical devices to the same SCSI controller.

**Types of Interfaces**

The two most common types of interfaces for attaching devices to the server are device-level interfaces and bus-level interfaces. The small computer system interface is a bus-level interface.

Each device connected to a device-level interface has a controller that is mounted on a separate adapter, away from the physical device. Usually, there are limitations on the types of devices you can attach to the same controller. Functions such as formatting, head selection, and error detection are directed by the controller and not by the device itself. The device is limited to performing the mechanical operations of reading and writing data, and it can do only what the controller allows it to do.

With a bus-level interface, each device has its own device controller that provides the details of how to accomplish its tasks. This type of interface uses a standardized set of commands, the Common Command Set, to issue tasks to the devices, and each device controller determines how to accomplish these tasks.
The Ultra SCSI controllers impose few restrictions on the number and types of devices that you can attach to them. As new SCSI devices become available, there is no need to install adapters. You can attach many different devices, such as hard disk drives, CD-ROM drives, scanners, and printers, to the same Ultra SCSI controller.

The SCSI standards allow great flexibility in the design of devices. Hardware manufacturers can develop SCSI devices to perform functions without requiring that the SCSI controller support those functions. Device drivers supplied by the device manufacturer provide support for the functions that are unique to the device.

**SCSI ID**

The SCSI ID is also known as the *SCSI address* or *physical unit number* (PUN). This address enables the SCSI controller to distinguish one device from another.

The SCSI controller can service only one device at a time. When more than one physical device is connected to the same SCSI controller, the devices compete for support from the SCSI controller. When this occurs, the SCSI controller gives each device a priority based on its SCSI ID.

The Ultra SCSI controllers in your server are preset to ID 7, and the backplanes are preset to SCSI ID 6. If your model came with one or more hard disk drives preinstalled, their SCSI IDs depend on where they are installed. See “Assigning SCSI IDs” on page 52 for information about how the backplane assigns SCSI IDs.

**Logical Units**

In addition to the physical unit number (PUN), each SCSI device also has at least one *logical unit number* (LUN). If a physical device supports no logical devices, its LUN is 0. Most SCSI devices support only LUN 0. However, some types of physical SCSI devices, such as *bridge controllers*, can support more than one logical device. The LUN identifies each device that is connected to the SCSI through its own device controller.
For example, a printer controller might support up to eight printers. The printer controller is a physical device, and each of the printers is a logical device. If the printer controller is set to ID 2, the ID of the first printer appears in the SCSI device configuration as PUN 2, LUN 0. The IDs of the other printers are PUN 2, LUN 1; PUN 2, LUN 2; and so on.

Assigning SCSI IDs

For the SCSI subsystem to function properly, each SCSI device installed in or attached to your server must have a unique SCSI ID.

Note: Devices attached to different controllers can use the same SCSI ID.

When you install additional hot-swap drives in bays 1 to 12, the backplanes (the printed circuit boards behind the bays) automatically set the SCSI IDs for the drives. Your server contains two backplanes, and each backplane supports up to six, SCSI hard disk drives.

The backplanes behind bays 1 to 12 assign the SCSI IDs as follows:

<table>
<thead>
<tr>
<th>Bay</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>

<th>11</th>
<th>12</th>
</tr>
</thead>

<td>11</td>
<td>12</td>
<td>13</td>
</tr>
</tbody>
</table>

*Table 1. Automatically Assigned SCSI IDs*

If the default SCSI ID settings assigned by the backplanes do not support your requirements, you can move the jumpers on the backplanes to change the SCSI ID assignments. See “Changing the Backplane SCSI ID Jumpers” on page 70 for more information.

Before you attach external SCSI devices or install a SCSI device in a removable-media bay, you must choose an ID for the device; then manually set the SCSI ID by following the instructions supplied with the device.

Your User’s Handbook contains more information about setting SCSI IDs, and it also contains detailed information about the types of drives that you can install in your server.
Cabling

The SCSI subsystem in your server consists of UltraSCSI controllers, SCSI devices, and cabling. The cabling (interface) conforms to the SCSI standards. SCSI cables for 16-bit devices have a set of 16 data lines, two data-parity lines, and various control lines. SCSI cables for 8-bit devices have a set of eight data lines, one data-parity line, and various control lines.

The server comes with two 16-bit SCSI cables.

In non-disk-array models, one cable goes from the UltraSCSI 1 connector on the system board to the top backplane and the other cable goes from the UltraSCSI 2 connector to the bottom backplane.

In disk-array models, one cable goes from the channel 1 connector on the PCI RAID adapter to the top backplane and the other cable goes from the channel 2 connector to the bottom backplane.

The interface uses daisy-chain cabling, where each device except the last one (internal or external) has one cable going into it and another coming out of it. There are some limitations on the length of cabling that you can use. Information about these limitations is provided in “Termination,” but more detailed information is provided in your User’s Handbook.

Termination

The SCSI standard defines the signals carried on the interface (cabling). To ensure the quality of these signals, a terminator must be present at both ends of the SCSI cabling. When both an internal cable and an external cable are present, the entire configuration is seen as one long bus. In this case, there are only two termination points, at the far ends of the internal and external cables.

The interface uses daisy-chain cabling, where each device except the last one (internal or external) has a cable going into it and another coming out of it. The last device has an incoming cable and a terminator.
In the PC Server 704, the hot-swap backplane automatically sets the termination of the drives. Therefore, you do not need to install or remove terminators when you install or remove hot-swap drives. However, if you install a SCSI device in one of the removable-media bays, or you attach SCSI devices to an external connector on a RAID adapter, you might need to adjust the termination so that the last device in the chain is terminated.

To ensure proper signal quality, maximum cable length and termination should conform to the ANSI SCSI Standards for your SCSI devices. The following general rules apply to SCSI-device termination:

- If you install a SCSI device in a removable-media bay and you attach one or more external SCSI devices, you must terminate the devices at the ends of the internal and external cables.
- If you have only one external device, you must terminate that device.
- For specific information about termination, use the instructions supplied with the device.

For more information, refer to the “Installing Options” chapter of the User’s Handbook.
Chapter 7. Disk Arrays

This chapter provides an overview of disk array technology and RAID levels, as well as the advantages of each level.

When you connect several hard disks together and configure the hard disk controller to access them in a predetermined pattern, you create a disk array. Disk arrays are used to increase security, performance, or reliability. They provide faster input and output rates than single large-capacity drives, because the files are stored on individually addressable disks and can be found more quickly during I/O requests.

The amount of security, performance, and improved reliability depends on the application programs that are running and the type of disk array you configure. The type of disk array you can configure depends on the data-storage patterns supported by your hard disk controller, operating system, and application programs.

Some PC Server 704 models come with a redundant array of independent disks (RAID) adapter preinstalled as a standard feature. This PCI RAID adapter enables you to configure RAID levels 0, 1, and 5 disk arrays.

If your server is a non-disk-array model, you can install a PCI RAID adapter and hard-disk drives to create a disk-array subsystem.

If your server came with a RAID adapter preinstalled, refer to the documentation that came with the adapter for detailed instructions about creating, deleting, and maintaining disk arrays.

**Improved System Performance**

When you group hard disk drives into a single logical drive, the RAID adapter can transfer data in parallel from the multiple drives in the array. This parallel transfer yields data-transfer rates that are many times higher than with non-arrayed drives. This increased speed makes the server better able to meet the throughput (the amount of work in a given amount of time) or productivity needs of the multiple-user network environment.
The ability to respond to multiple data requests provides not only an impressive increase in throughput, but also a decrease in response time. The combination of parallel transfers and simultaneous responses to multiple requests allows disk arrays to provide the highest level of performance in network environments.

**RAID Technology**

RAID is the technology of grouping several hard disk drives in a server into an *array* that you can define as a single *logical* drive. This logical drive then appears to the operating system as a single physical drive.

RAID technology provides access and data transfer rates beyond the physical limitations of existing hard disk drives, which greatly enhances the system-drive capacity and performance.

In addition, if one of the physical drives in a RAID level-1 or RAID level-5 disk array fails, the system continues to run, with no operator intervention required. You can replace the failed drive without turning off the server (hot-swap), and the RAID adapter rebuilds the new drive contents from the information on the other drives. This rebuilding process takes place in the background with the system online. Once the drive contents are rebuilt, full performance and fault-tolerant functions are restored.

*Note:* Data stored in a failed level-0 logical drive is lost.

**Logical Drives**

The following information will help you understand how the server manages logical drives and how many you can define.

When you create an array, you group hard disk drives into one storage area. You can define this storage area as a single logical drive, or you can subdivide it into several logical drives. A logical drive in an array can be any size you choose within the size limitations of the array. The number of logical drives and arrays that your server supports depends upon the RAID adapter installed.
If you have only one array, you can define it as a single logical drive, or you can divide it into several logical drives. If you have two or more arrays, each array can be one logical drive, or you can divide each array into multiple logical drives, as long as the total number of logical drives for all of the arrays does not exceed the number of logical drives supported by the RAID adapter.

The operating system considers each of these logical drives just as it does a physical hard disk drive. You can use the FDISK program (or its equivalent) to partition the logical drives in the same way that the operating system partitions a hard disk drive.

If you install an operating system, you can allow the installation program to determine how the FDISK program or its equivalent allots the space within a logical drive, or you can manipulate the program yourself to partition the available space. For more information, refer to your RAID adapter documentation and your operating system documentation.

**Additional Storage Capacity**

When you add hard disk drives to your server, you must configure a new array before you can use the drives. You can reconfigure an existing array to include the capacity offered with the new drives, or you can group the new drives into their own array. You also can create an array with only one drive. Your server has space for up to 12 hot-swappable hard disk drives. You can install additional SCSI devices in the four removable-media bays, but these bays do not support hard disk drives or hot-swapping. Depending upon your configuration, you might need to install an additional cable.

**Notes:**

1. Before you reconfigure or redefine an existing array, be sure to back up your data. When you redefine an existing array, all data in that array is lost.

2. The RAID adapter automatically assigns RAID level 0 to all logical drives in an array containing only one hard disk drive.
Hard Disk Drive Capacities
Hard disk drive capacities influence the way you create arrays. Drives in the array can be of different capacities (1 GB or 2 GB, for example), but the RAID adapter treats them as if they all have the capacity of the smallest disk drive. For example, if you have four drives of 1 GB, 1 GB, 1 GB, and 2 GB grouped into one array, the total capacity of the array is 1 GB times 4, or 4 GB, not the 5 GB physically available.

If you add a smaller drive to an array of larger drives, such as a 1 GB drive to a group containing three 2 GB drives, the total capacity of that array is 4 GB, not the 7 GB physically available.

Disk-Array Classifications
With RAID technology, data is striped across an array of hard disk drives. This data-distribution technique complements the way the operating system requests data.

The six basic disk-array classifications are RAID-0 through RAID-5. The PCI RAID adapters available for your PC Server 704 support three, industry-recognized RAID levels: 0, 1, and 5.

RAID Level 0
RAID level 0 stripes the data across all the drives in the array. This offers substantial speed enhancement, but provides for no data redundancy. The RAID adapter automatically assigns RAID level 0 to all logical drives in an array containing only one hard disk drive.

A hard disk failure within the array results in loss of data in the logical drive assigned level 0, but only in that logical drive. If you have logical drives assigned RAID level 1 or 5 in the same array, they will not lose data.

* When referring to hard drive capacity, MB stands for 1,000,000,000 bytes and GB stands for 1,000,000,000,000 bytes. Total user-accessible capacity may vary depending on operating environments.
When you replace the failed drive, the RAID adapter automatically rebuilds all the logical drives assigned RAID levels 5 and 1 onto the replacement hard disk drive and defines the level-0 logical drive. However, the data that was in the failed level-0 logical drive is lost.

Though the risk of data loss is present, you might want to assign RAID level 0 to one of the logical drives to take advantage of the speed offered with this level. You could use this logical drive to enter data that you back up each day and for which safety is not of primary importance; that is, data that you can re-create easily. You also might want to use a level-0 logical drive when the work you are doing requires maximum capacity. Level 0 provides the largest capacity of the three RAID levels offered, because no room is taken up for redundant data or data parity storage.

In the event of a drive failure in an array that contains a logical drive assigned RAID level 0, the RAID adapter will not activate a hot-spare drive.

**RAID Level 1**

RAID level 1 provides 100% data redundancy and requires two hard disk drives. With RAID level 1, the first stripe is the data stripe; the second stripe is the *mirror* (copy) of the first stripe, but written to another drive. If one of the hard disk drives fails, the RAID adapter switches read and write requests to the remaining functional drive in the array.

Because the data is mirrored, the capacity of the logical drive when assigned level 1 is 50% of the physical capacity of the grouping of hard disk drives in the array.

RAID level 1 requires two drives. When you group more than two drives into a RAID level-1 array, the RAID adapter will either automatically assign the enhanced RAID level 1 to the array, or it will allow you to assign the enhanced (0+1) level to the array.

The enhanced RAID level 1 stripes data and copies of the data across all the drives in the array. As with the standard RAID level 1, the data is mirrored, and the capacity of the logical drive is 50%
of the physical capacity of the grouping of hard disk drives in the array.

The following illustration shows data arranged in an array with three hard disk drives. The logical drive is assigned the enhanced level 1. Notice that the mirror of the first data stripe (XXX YYY ZZZ) is shifted one drive. The other data stripes in level 1 follow the same pattern.

<td>Mirrored stripe</td>
<td>CCC</td>
<td>AAA</td>
<td>BBB</td>
</tr>
</tbody>
</table>

Table 2. Enhanced RAID Level 1

If you have only two drives available, the second drive is a mirror copy of the first drive.

**RAID Level 5**

RAID level 5 stripes data and parity across all drives in the array. When an array is assigned level 5, the capacity of the logical drive is reduced by one drive (for data parity storage).

Level 5 is generally the most desirable choice, because it offers both data protection and increased throughput. Level 5 gives you higher capacity than level 1, but level 1 offers better performance. If after using level 5 you are dissatisfied with the performance and can tolerate lower capacity, you can backup the data stored in the array, and then redefine the level to level 1; or, you can use a logical drive that you have assigned level 1.

*Note:* Before you reconfigure or redefine an existing array, be sure to back up your data. When you redefine an existing array, all data in that array is lost.
If you want to have a hot-spare drive and also assign level 5, you must have at least four hard disk drives, with no logical drives assigned level 0.

**RAID Adapter Features**

The PCI RAID adapters available for your server support:

- A 32-bit PCI data bus
- A 4MB adapter cache, which significantly improves server performance by keeping frequently used SCSI-device data available for immediate transfer
- SCSI Tagged Command Queuing
- *Hot-spare drives*, which enable the disk-array subsystem to perform data recovery and data reconstruction automatically, in the event of a single disk failure in a level-1 or level-5 array

See the documentation that came with your RAID adapter for more specific information.

**Overlapped Input/Output Operation**

The RAID adapter available for your server provides multiple data paths to and from arrayed drives. This enables your server to respond to requests from several users simultaneously. If one user requests data that resides on the first drive in the array and a second user requests data that resides on the second drive, the RAID adapter can deliver the requested data to both users simultaneously.

**Interleave Depth/Stripe Unit**

The granularity at which data from one file is stored on one drive in the array before subsequent data is stored on the next drive in the array is called the *interleave depth*. For optimum system performance, you can set the interleave depth to a unit size of from 8 KB to 64 KB of data. The collection of these units in logical order, from the first drive in the array to the last drive in the array, is called a *stripe*. 

Chapter 7. Disk Arrays 61
Queue Depth
Commands are queued in the RAID adapter. To obtain better performance, the commands in the queue will be reordered and coalesced on a hard disk drive basis. That is, the adapter organizes the commands according to which drive will be responding, and then orders and combines two or more commands, when possible, before sending them to the drives.

Cache
The RAID adapter available for your server has cache memory. You can configure this cache memory to operate in write-through or write-back mode on a logical-drive basis. Cache memory has parity to detect memory errors and retry algorithms to recover from errors that appear sporadically. For more information, see “Cache Memory” on page 34 and your RAID adapter documentation.

Hot-Spare Drive Replacement
A hot-spare drive is any hard disk drive defined for automatic use in the event of a drive failure. The hot-spare drive must be of equal capacity to or greater capacity than the drives in the array it is intended to replace. You can define multiple drives as hot-spare drives.

If a hard disk drive fails in a RAID level-1 or RAID level-5 array, the RAID adapter automatically re-creates the data from the failed drive on the hot-spare drive. When you replace the failed drive and run the operating-system-specific utility program, the RAID adapter will automatically define the replacement drive as your new hot spare.

Data Protection
The RAID adapter provides the server with a data redundancy technique that distributes data across all the drives in the array. In the event of a single drive failure in a RAID level-1 or RAID level-5 array, the remaining drives in the array service read and write requests, without loss of data. The failed hard disk drive appears to be operating correctly, although at reduced performance.
When you replace the failed drive, the data in logical drives assigned RAID levels 1 and 5 is rebuilt on the new hard disk drive, using the parity information stored on the other hard disk drives in the array. You must replace and rebuild the failed drive in a timely manner to avoid multiple-drive failures and reduced performance. Once the RAID adapter rebuilds the drive contents, full performance and fault-tolerance functions are restored.
Chapter 8. Configuration

You play a key role in how your server allocates resources to hardware devices and software programs. This resource-allocation process is referred to as configuration. The steps required to configure your server depend on the PC Server 704 model you have, the number and variety of devices you install, and the software programs you install.

Your server has the flexibility and power to support several types of adapters and devices. Depending upon your model, this flexibility lets you choose from among thousands of adapters and devices that comply with the following standards:

- Peripheral component interconnect (PCI)
- Enhanced industry standard architecture (EISA)
- Industry standard architecture (ISA)
- Small computer system interface (SCSI)

The System Configuration Utility is PCI and Plug-and-Play aware, and it complies with the EISA Specification (version 3.12) and the ISA Plug-and-Play Specification (version 1.1).

In general, the greater the number and variety of hardware devices and software programs that you install, the more you will have to interact with your server and your devices to correctly configure your system.

Power-On Self-Test

Each time you turn on your server, it performs a series of tests that check the operation of the server and some options. This series of tests is called the power-on self-test (POST). The POST checks the system board, microprocessors, memory, video, keyboard, and most of the installed devices. During the memory test, the screen displays a number that represents the amount of available server memory.

Note: When you use the Ctrl+Alt+Del key sequence to restart the server, the POST does not run the memory test.

For PCI, EISA, and ISA devices, your server uses configuration programs and configuration files to assign interrupt levels,
input/output addresses, memory addresses, and other server resources. However, your system automatically recognizes and configures other options, such as memory and plug-and-play adapters.

**Configuration Programs**

All PC Server 704 models come with menu-driven configuration programs. These programs enable you to view or change:

- System-board settings and assignments
- PCI, EISA, and ISA device assignments
- SCSI device assignments
- Disk array assignments (some models)

The types of configuration programs provided with your server depend on your model. Step-by-step instructions for using most of the PC Server 704 setup, configuration, and utility programs are provided in your *User’s Handbook*. Instructions for using the SCSI configuration programs are provided in your *SCSI Software User’s Guide*. If your server came with a RAID adapter installed, see the RAID adapter documentation for configuration information.

The PC Server 704 comes with the following configuration programs:

- **System Configuration Utility Programs**
  
  These menu-driven programs are the primary method for configuring your server and optional devices. The programs on the System Configuration Utility Diskette enable you to view or change your server’s configuration information. You should run these programs when you first set up your server; when you get a configuration error during startup; or when you install, remove, or change the position of a device in the server.

  Before you install a new device or program, or make changes to your existing configuration, be sure to start the System Configuration Utility programs and record the current settings. In the unlikely event that a conflict occurs, you will be able to change the settings back to their original values.
• **Built-in Setup Program**

All PC Server 704 models come with a built-in Setup program, which you can access during system startup. This program is stored in nonvolatile RAM on the system board.

You can use this program to set the date and time, set passwords, or to enable or disable the diskette drive.

The built-in Setup program also enables you to view or change system-board settings. However, you should use the System Configuration Utility programs to accomplish these tasks because they provide conflict-resolution support and access to information about ISA, EISA, and PCI devices.

• **SCSISelect Program**

The SCSISelect configuration program comes with all PC Server 704 models. It enables you to view or change the assignments of SCSI devices attached to the two SCSI controllers on the system board. You can use this utility program to change default settings, resolve configuration conflicts, or perform a low-level format on a SCSI hard disk drive connected to the integrated UltraSCSI controllers. See “The SCSISelect Utility Program” on page 68 and your *SCSI Software User’s Guide* for more information.

• **RAID Configuration and Monitoring Programs**

The PCI RAID adapter diskettes come with disk-array models. These diskettes contain device drivers, monitoring programs, and menu-driven configuration programs that enable you to define, create, modify, or delete your disk arrays. The programs on these diskettes also enable you to view or change the SCSI device assignments for the drives attached to the RAID adapter. See your RAID adapter documentation for more information about defining or changing your disk-array configuration.
The SC SilS Select Utility Program

The UltraSCSI controllers on the system board come with a menu-driven configuration program that enables you to view or change SCSI settings. You can use the SC SilS Select program to change default settings, locate and correct configuration conflicts, and format a new SCSI hard disk.

The settings that you can view or change include:

- **Host Adapter SCSI ID**
  You can change the SCSI ID of the UltraSCSI controllers from their default value of 7.

- **SCSI Parity Checking**
  You can enable or disable parity checking on the UltraSCSI controllers. The default setting is *Enabled*.

- **Host Adapter SCSI Termination**
  You can change the termination of the UltraSCSI controllers. The default setting is *Low On / High On*.

- **SCSI Device Configuration**
  This enables you to configure SCSI device parameters. Before you can make updates, you must know the ID of the device whose parameters you want to configure.

- **Advanced Configuration Options**
  This enables you to view or change the settings for advanced configuration options.
Configuration Process Overview

When you install a new device or change the position of an existing device, you might need to reconfigure your server. The steps required to configure your server depend on the option you install.

Configuring SCSI Devices

When you install hot-swap drives, the SCSI ID for the drive is assigned by the backplane behind the bay. The backplane also manages the termination of the hot-swap drives. However, if you attach an external SCSI device or install a SCSI device in a removable-media bay, you will need to manually set the SCSI ID and termination for the device. Check the documentation that came with the device for instructions to set the SCSI ID and termination for the device. See “Assigning SCSI IDs” on page 52 and “Termination” on page 53 for more information.

The backplanes behind bays 1 to 12 assign the SCSI IDs as follows:

Changing the Backplane SCSI ID Jumpers

If the default SCSI ID backplane assignments do not support your requirements, you can move the J3 and J4 jumpers on the backplanes to change the SCSI ID assignments.

The top and bottom backplanes are identical, and each backplane has its own J3 and J4 jumpers. The jumpers do not need to be set the same way for each backplane. However, keep in mind that the backplanes are set to SCSI ID 6. The top backplane supports Bays 1 through 6, and the bottom backplane supports Bays 7 through 12. The following illustration and table show the location of the J3 and J4 jumpers and the alternative settings.

Table 4. Changing the Backplane SCSI ID Jumpers
Configuring EISA, ISA, and PCI Adapters

During startup, the server’s basic input/output system (BIOS) code detects EISA, ISA, and PCI devices and automatically assigns system resources as follows:

1. ISA devices: If found and recognized, the server initializes and assigns resource priority over other devices of the same type to the ISA devices.
2. EISA devices: If found and recognized, the server uses predefined parameters to initialize and assign resources.
3. Optional PCI devices: If found and recognized, the server uses predefined parameters to initialize and assign resources.
4. Built-in PCI devices: The server uses predefined parameters to initialize and assign resources.

For PCI, EISA, and ISA devices, your server uses configuration programs or configuration files to assign interrupt levels, input/output addresses, memory addresses, and other server resources. In most cases, the server will operate using the default settings. However, in the event that you install a EISA or ISA device that is not recognized, you should refer to the instructions in “Configuring EISA or ISA Adapters.”

Configuring EISA or ISA Adapters

Before you install an EISA or ISA adapter in your server, be sure to check the documentation that came with the adapter. Some adapters have jumpers or switches that you must set to assign system resources, such as interrupt levels and memory addresses. Before you assign a system resource to the adapter, you must verify that the resource is not already assigned to the system board or another device. To do this:

1. Check the adapter’s documentation to see which system resources, such as interrupt level or memory-address space, it needs to function properly.
2. Start the System Configuration Utility programs.
3. Record the settings of the existing devices.

4. Compare the settings of the existing devices to the settings required by the new adapter; then choose settings for the new adapter that will not conflict with an existing device.

Some adapter documentation might list only one choice for a system resource. For example, the adapter might operate only at interrupt level 3. If this occurs, you might need to change the assignment of an existing device to avoid a configuration conflict.

5. Set the jumpers or switches on the new adapter.

6. Install the new adapter in an available expansion slot.

7. Use the System Configuration Utility programs to create a custom configuration file (.CFG) for the device, or to assign or verify the adapter's configuration.

**Configuring PCI Adapters**

Programmable configuration hardware enables your server to recognize and configure PCI adapters automatically. This programmable hardware consists of:

- Nonvolatile RAM on the system board
- Hardware used to store the device ID
- Registers on the system board and adapters

Instead of jumpers and switches that you set manually, the PCI adapters have registers that act as electronic switches. These read and write registers are set by the POST routine each time you turn on the server. The registers are volatile storage areas, and retain the configuration information only while the server is turned on. When you turn off the server, the configuration information is cleared from these registers.

A current copy of the configuration information is stored in a battery-backed memory area known as nonvolatile RAM. The same battery that supports the nonvolatile RAM module supports the real-time clock module, which provides a time-of-day clock, a 100-year calendar, and 64 bytes of nonvolatile RAM that the server uses to store some setup information, such as passwords.
Each PCI adapter has a unique device ID. The POST routine uses the device ID to identify the type and location of each PCI adapter in the server.

The programmable configuration hardware, together with the configuration programs and configuration files, simplifies the process of configuring PCI devices by:

- Eliminating the need for setting jumpers and switches on PCI adapters
- Enabling you to configure the server automatically or manually using menu-driven programs
- Identifying the type and location of each device in the server
- Resolving server resource conflicts

**Option Diskettes**

The configuration files for an optional device normally are provided on an Option Diskette that comes with the device. The server uses these configuration files to assign settings that define how the device will operate. Sometimes Option Diskettes also contain device drivers and diagnostic programs for the device.

Whenever you install a device that comes with an Option Diskette, be sure to read the instructions that come with the device. Refer to the information provided with the option, the instructions provided in your *User’s Handbook*, and your operating system documentation to install the device-specific files provided on the Option Diskette.
Chapter 9. Input/Output Ports and Connectors

The input/output (I/O) connectors are for attaching external devices, such as printers, keyboards, and displays, to your server. The I/O connectors on the PC Server 704 include:

- Two serial-port connectors
- One parallel-port connector
- One video-port connector
- One keyboard-port connector
- One auxiliary-device-port connector
- SCSI-port connectors (vary by model)

Serial Ports

Your server comes with two serial ports. These ports are used to communicate with printers, plotters, external modems, scanners, and auxiliary terminals. These ports also enable you to transfer data between computers.

Serial ports transfer data one bit at a time, using direct memory access (DMA). DMA is a method of transferring data between I/O devices and system memory without intervention by the system microprocessor. See “Direct Memory Access” on page 31 for more information.

Serial ports can transfer data asynchronously, which means that they can transmit any number of characters at any time, with no restriction on the duration of the pauses between characters.

The serial ports can transmit and receive data and commands at rates of from 300 bits per second up to 345,600 bits per second. To use a serial port at 345,600 bits per second, you need a special shielded cable. For information about this cable, contact your IBM marketing representative or your IBM authorized reseller.
Each serial port has a 9-pin, male D-shell connector on the back of the server. The pin-number assignments of this connector conform to the RS-232C industry standard.

The following table shows the pin-number assignments for the serial-port connectors.

Table 5. Serial Port Pin-Number Assignments

When you turn on your server, the POST routine assigns the serial ports to specific communication port addresses.

Some application programs use only certain ports, and some modems are designed for use only at certain communication port addresses. You might need to change communication port address assignments to resolve conflicts by using the System Configuration Utility programs.
Parallel Port

The parallel port usually is used to communicate with printers, and transfers data one byte at a time using DMA. The parallel port has a 25-pin, female D-shell connector on the back of your server.

The following table shows the pin-number assignments for the parallel-port connector.

UltraSCSI Ports

All PC Server 704 models come with two UltraSCSI bus-master controllers on the system board. Each of these controllers supports up to 15 SCSI devices. The 68-pin SCSI connectors for these controllers allow you to expand the capabilities of your server by attaching different types of SCSI devices, such as drives or printers.

The PCI RAID adapter, that comes preinstalled as a standard feature in disk-array models, has three independent channels. Each channel supports up to 15 SCSI devices.
The following table shows the pin-number assignments for the 68-pin SCSI connectors.

Chapter 10. Video Subsystem

The IBM PC Server 704 comes with a super video graphics array (SVGA) controller on the system board. This controller uses a 15-pin, analog video connector. For information about the video connector, see “Video Port” on page 78.

This video controller supports high resolution graphics and fast refresh rates that meet the specifications of the ISO 9241 Part 3, Visual Display Requirements. It also provides reduced-flicker operation when used with noninterlaced monitors that meet ISO standards. For more information, see “How Monitors Operate” on page 82.

The SVGA controller includes a video display buffer with 512 KB of video dynamic random access memory (DRAM). You can increase the amount of video memory in your server to 1 MB by installing an additional 512 KB (256 K by 16-bit), 70 ns CMOS DRAM module with Fast Page Mode, such as Samsung KM416C256AJ-7, Hitachi HM514260AJ7R, or equivalent.

The amount of video memory in your server determines the resolution and the number of colors supported. Additional features of the SVGA controller include:

- Integrated VGA emulation
- Compatible with CGA, EGA, and Hercules Graphics
- 132-column text mode support (with 1 MB of video DRAM)
- Screen resolutions with 512 KB of video DRAM:
  - 640 x 480 pels with up to 256 colors
  - 800 x 600 pels with up to 256 colors
  - 1024 x 768 pels with up to 16 colors
- Screen resolution with 1 MB of video DRAM:
  - 1280 x 1024 with up to 16 colors
  - 1024 x 768 with up to 256 colors
- Support for analog monitors (single and multiple frequency, interlaced and noninterlaced) with a maximum frequency of 87 Hz

Depending upon your operating system, you might need to install some video device drivers. Refer to the documentation that came with your operating system for more information.
How Monitors Operate

The most common distinguishing characteristics of monitors are resolution, dot pitch, vertical-refresh rate, screen size, and color.

Resolution and Dot Pitch

If you look closely at the screen, you can see that the entire image is made up of many tiny dots, called pels. Resolution is measured by the number of pels needed to fill the screen (horizontal-by-vertical).

Dot pitch is more difficult to visualize. The inside of the monitor screen is coated with light-emitting materials called phosphors. Color monitors use three phosphors: red, green, and blue. The phosphor coating is made up of dots arranged in a red-green-blue pattern. The distance from the center of one phosphor dot to the center of the next phosphor dot of the same color is called the dot pitch. Dot pitch is measured in millimeters, such as 0.28, 0.31, and 0.41.

In general, the monitor with the highest resolution and finest dot pitch produces the sharpest image. A monitor with a fine dot pitch, such as 0.28, produces sharper, better defined characters than a similar monitor that uses a coarser dot pitch, such as 0.41.

These characteristics can be very important. A system used extensively for detailed graphics might need a monitor that shows more colors, at a higher resolution and finer dot pitch, than one used exclusively for word processing. For some applications, a black-and-white (monochrome) monitor might do as well as a color monitor.
Vertical-Refresh Rate

The phosphors on the inside of the monitor screen hold their brightness and color for a very short time. Therefore, the image has to be redrawn many times each second to refresh the phosphors. The vertical-refresh rate is the speed at which the image on the screen is redrawn.

The image is redrawn from top to bottom. By the time the bottom rows are drawn, the top rows are starting to fade. The two ways of redrawing the image are interlaced and noninterlaced. The interlaced method draws every other row from top to bottom, then starts at the top to fill in the rows that were skipped on the first pass. The noninterlaced method draws the complete image on each pass.

The vertical-refresh rate affects the stability of the image on the screen. Monitors that have a fast, noninterlaced refresh rate provide a very stable image with little or no flicker detectable. Monitors with slower refresh rates tend to have more flicker, which is particularly noticeable with white and other light-colored backgrounds. You can minimize the flicker by changing the colors you work with. Many programs allow you to select colors.

Sensitivity to flicker varies from person to person, with young people being the most sensitive. Noninterlaced flicker occurs when the screen is redrawn at a rate that is slow enough to be detected by the human eye. Interlaced flicker occurs when the pattern of pels in adjoining lines is very different, or when an object on the screen is made up of alternating bright and dim lines.

Some application programs cannot reproduce all colors, and use a technique called dithering to combine two colors. For example, light red might be produced by alternating lines of white and red. As the image is continually refreshed using the interlaced method, the red lines are drawn on one pass and the white lines on the next pass. As a result, the light-red object might appear to flicker while the rest of the image on the screen remains stable.
Selecting a Monitor

Monitors come in many sizes and types. The video controller in your server supports a wide range of monochrome and color monitors with various capabilities.

IBM provides many monitors that you can use with your system. To take full advantage of the video capabilities provided by your server, use a monitor with a fast noninterlaced refresh rate, such as the IBM G40, G50, or P50 monitor.

The following table provides a partial list of monitors and their characteristics.

Using Your Monitor

The following information will help you use your monitor comfortably and correctly.

Brightness and Contrast Controls
Use the brightness and contrast controls to adjust the image on the screen for maximum viewing comfort. On a new monitor, set the controls near their center position. Setting these controls to their maximum position can decrease the useful life of the monitor.

As the monitor gets older, the image tends to become dimmer. Adjust the brightness and contrast controls to compensate for this condition.

Screen-Saver Programs
Leaving the monitor turned on for prolonged periods without changing what appears on the screen can have an adverse affect on the monitor. The image might burn into the phosphor coating, leaving a permanent image, or cause darkening of some areas of the screen.

You can avoid this problem by using a screen-saver program. This turns off the video signal when the keyboard has not been used for a defined period. When you are ready to work with the system again, pressing a predefined key restores the image to the screen. Several companies produce screen-saver programs. Contact your IBM marketing representative or your IBM authorized reseller.
Avoiding Fatigue
Performing any visually demanding task for a prolonged period of time (for example, knitting, reading, or viewing a monitor screen), can cause eye fatigue. The American Academy of Ophthalmology considers monitors safe for normal use and has declared they present no hazard to vision and do no damage to the eye. To minimize eye fatigue, reduce any annoying glare and make sure your vision is properly corrected. If eye discomfort persists, consult your eye-care professional or physician.

Similarly, sore muscles or joints can result from any job or activity during which you stay in a fixed position or repeat the same movement over a long period. This is not unique to viewing a monitor screen. Eye fatigue and sore muscles and joints can be reduced by modifying work practices. Take breaks, rotate tasks, and adjust the monitor, lighting, and chair height.

See your User’s Handbook for additional information.
Chapter 11. Security Features

Security features deter unauthorized use of your server and data. If you use your server in a public environment, such as an office, you might want to protect it and the data stored on it by using one or more of the PC Server 704 security features.

Begin by evaluating your security needs. Where will the system be located? Should access to the server's internal physical devices, such as hot-swap drives, adapters, and memory be limited? Should use of the system or configuration programs be limited? When you have identified your security needs, you can activate or implement the appropriate security features.

This chapter contains information about the hardware and software security features that come with the PC Server 704. This chapter also provides information about the methods you can use to secure the data stored on your server.

Hardware Security Features

One method of deterring access is to locate critical resources, such as servers, in a limited-access area behind locked doors. Keylocks and padlocks also help prevent unauthorized access.

This section provides information about the built-in hardware security features on your PC Server 704. These features consist of a keyed door and three padlock loops.

Door Lock and Key
A door lock mechanically deters access to the drives. It controls access to the small door that covers the removable-media bays as well as the entire front cover. Always store your key in a safe place.

Padlock Loops
If your server is in an area accessible to the public, you might need a method of limiting access to the server's internal physical devices, such as hot-swap drives, adapters, and memory. Your PC Server 704 comes with three padlock loops. See “Padlock Loops and Power Supplies” on page 14 for the location of the padlock loops.
The two side cover padlock loops enable you to insert padlocks (not provided) to secure the top and side covers to the system unit.

The EMI panel on the front of the server also has a padlock loop. You can insert a small padlock (not included) through this loop to secure the EMI panel to the system unit and help prevent unauthorized access to the hard disk drives in the hot-swap bays.

Software Security Features
This section provides information about the software security features provided with your PC Server 704. These features consist of:

- User password
- Administrative password
- Features provided in the Security Subsystem

User Password
The user password locks the keyboard and mouse (if attached to the mouse port) to help prevent unauthorized use of your server. If you are using a mouse that is connected to the serial port, the mouse remains active.

You do not need to set a user password to use your server, but a password helps protect the data you store on your server. Keep a record of your password in a secure place.

Your password can be up to seven alphanumeric characters. You must run the built-in Setup program to define your password; then, start the System Configuration Utility programs and enable the user-password feature. See your User's Handbook for instructions.

After you define and enable the user password, you must enter your password during system startup or when the keyboard inactivity timer expires. The keyboard and mouse (if attached to the mouse port) will remain locked until you enter your password.
Administrative Password

Using this security feature allows you to control who has access to the built-in Setup program and the System Configuration Utility programs. If an administrative password is set, you must enter the password before you can use the configuration programs.

After an administrative password is set and the covers are secured with padlocks, only those who know the password can alter the server’s configuration settings and features.

Note: The padlocks prevent access to the system configuration switches on the system board.

Your administrative password can be up to seven alphanumeric characters. You must run the built-in Setup program to define your password; then, start the System Configuration Utility programs and enable the administrative-password feature. See your User’s Handbook for instructions.

After you define and enable the administrative password, you must enter your password to access the built-in Setup program or the System Configuration Utility programs.

Security Subsystem Features

The PC Server 704 comes with utility programs that enable you to enable or disable some of the PC Server 704 security features. You can access most of these features through the System Configuration Utility programs. They are located in the Security Subsystem or the Boot Subsystem sections in the Peripheral Configuration Group.

In addition to the user and administrative password features, the System Configuration Utility programs provide access to the following security features:

- Keyboard-lockout timer
- Secure mode
- Drive-startup sequence
**Keyboard Lockout Timer**

This feature is useful if you leave your system on and unattended. With the keyboard and mouse ports locked, no one can use your system. When the keyboard and mouse ports are locked, the system automatically write protects the diskette drive.

The keyboard-lockout timer allows you to specify an inactivity time-out period of 1 to 128 minutes (in one minute intervals). If you enable the timer and there is no keyboard or mouse activity during the specified period, the following occurs:

- Keyboard and mouse input is inhibited
- A blank screen appears on the monitor
- The diskette drive (if enabled) becomes write-protected

You must enter your user password to unlock the keyboard and mouse.

**Secure Mode**

After you set a user password, you can enable the secure mode. This mode locks the power-on button, reset button, keyboard, and mouse; but it allows the system to start the operating system and carry out the instructions in the CONFIG.SYS and AUTOEXEC.BAT files. The keyboard and mouse remain locked until you enter the correct user password.

This mode is ideal for systems that operate unattended. If a power failure occurs, the system automatically restarts when power returns, and resumes normal operation without operator intervention. By disabling the power-on and reset buttons on the front of the server, this mode also protects against an accidental power-off or reset of the server.

When enabled, this feature prevents tampering with the configuration settings and stored data. If both user and administrative passwords are set, the secure mode prevents access to the configuration programs provided in ROM and on the System Configuration Utility Diskette. When you enable the secure mode, you can choose to enable or disable writing to a diskette. You also can activate a hot-key combination that allows you to put the system
into the secure mode immediately, instead of waiting for the keyboard-inactivity timer to expire.

See your *User’s Handbook* for more information.

**Drive-Startup Sequence**

The Boot Subsystem section in the Peripheral Configuration Group allows you to control the startup sequence of the drives in your server. Each time you turn on the server, it checks the drives as it looks for the operating system. The order in which the system checks the drives is the *drive-startup sequence*.

The default drive-startup sequence checks the primary diskette drive for a self-starting diskette. If one is present, the operating system or program is loaded from the diskette. If not, the system checks the primary hard disk for an operating system. If one is present, it is loaded from that hard disk.

If you start the system from a diskette, the drive containing the diskette becomes drive A, regardless of the defined sequence, and the first hard disk selected in the startup sequence becomes drive C. You can choose a startup sequence of up to four drives.

You can *customize* the startup sequence by changing the order in which the system checks the drives. You decide which four drives are the first to be checked, and the order in which the system checks them.

*Note:* If you change your startup sequence, be extremely careful when doing *write* operations (such as copying, saving, or formatting). You can accidentally overwrite data or programs if you select the wrong drive.

In most cases, you do not need to change the default drive-startup sequence. However, if you are working with multiple hard disk drives or multiple operating systems, you might want to change the default drive-startup sequence. The default drive-startup sequence includes the diskette drive. To increase security, you can remove the diskette drive from the startup sequence. To further increase
security after you configure your system, you can disable the diskette drive completely using the built-in Setup program.

### Securing Data

It is very difficult to secure shared information from theft, but an effective method is to limit user access. Only users who need the software or data should be able to access it. This level of access control is provided as a standard feature of most network programs. Another common feature of network programs to help secure data from theft is password protection. Passwords are easy to use and very effective. They help prevent unauthorized users from accessing sensitive files.

Some advanced network management programs can actually audit usage based on names, adapter addresses, date, time, and unsuccessful attempts to access a file. This information can help you identify users who are attempting to access restricted data.

To secure extremely sensitive data, you can use a commercially available data-encryption tool. These tools encode the data files so that they are unintelligible, and thus useless if stolen. You can encrypt data by using a program or using an encryption device. The software programs are usually less expensive than the hardware devices, but they are slower.

### Protecting Data from Loss

You can use several methods to prevent the loss of data. Consider these methods carefully, because some of them affect the performance, reliability, and hardware requirements of the server.

The three primary ways to protect your data from loss are:

- Wait until the data accumulates on the server, and then make backup copies of all the hard disks.
- Configure a RAID level 1 disk array (disk mirroring) to duplicate the data as it is entered.
• Configure a RAID level 5 disk array and store the parity information about the data on the array as the data is being entered.

Backup Copies
A good method for preventing the loss of data is to make copies of the data. That way, in the event of a hardware failure, you can always recover the information.

Backing up the entire contents of a hard disk to diskettes can be very time-consuming and, in the case of a network server that has multiple hard disks, might require hundreds of diskettes. A faster and more efficient way to back up the data is to use a tape-backup drive. Using a tape-backup drive, you can copy several billion bytes of data from the hard disks to a single tape.

There are two problems with making backup copies. First, someone has to remember to do it. And second, you usually need to disconnect the server from the network to make the backup copies.

Redundant Copies
A convenient way to copy the contents of a hard disk is to duplicate all data as it is being entered (such as with a RAID level-1 disk array). This duplicate copy is then stored on another hard disk. If one hard disk fails, you still have access to the data on the other. This method is more expensive than backing up to diskettes or tapes, because it doubles the amount of disk space needed. See "RAID Level 1" on page 59 for more information.

Parity Information
Storing parity information about the data as the data is being entered (such as with a RAID level-5 disk array) is an efficient, cost effective, and reliable method commonly used to guard against the loss of data. In the event of a hard disk failure, the parity information and the data on the remaining functional disks are used to reconstruct the data that was stored on the failed drive. See "RAID Level 5" on page 60 for more information.
Viruses

Computer viruses are a problem that exists within the personal computer community. A virus is a program (or instruction hidden within a program) that infects other programs by modifying them without your knowledge. Like any other program, the virus can do anything it is programmed to do. Some viruses are practical jokes, causing unusual or erratic screen behavior. Others are destructive, erasing or damaging files or overloading memory and communication networks.

Viruses are difficult to detect. Many stay inactive until triggered by a specified event such as a date or command. Others are activated when an infected program is started a specified number of times. When the symptoms of the virus appear, it might be difficult to determine if the problem is a hardware failure, a problem in the software, or a virus.

Several programs are available to detect viruses. They typically examine files and look for patterns associated with these viruses, or look for unexplained changes in the size of files. These programs are best used as a preventive measure to detect a virus before it becomes widespread or causes damage. Many computer users check for viruses on a regular basis.

When a virus is found, it must be removed. This might be as simple as replacing a file, or it might require the assistance of a trained technician.

Viruses are generally spread unknowingly from computer to computer when programs are exchanged or shared. If you don’t know where a program came from, be careful. Most reputable program distributors and bulletin-board owners scan their files to guard against viruses and maintain records to identify program owners.

These tips will help you guard against computer viruses:

- Write-protect original program diskettes before using them. This ensures the diskettes will not be infected if a virus is already present in your system.
• Avoid using programs and diskettes from unknown sources.
• If you use programs provided from public-domain software distributors or bulletin-board services, find out what precautions they take to guard against viruses.
• Back up all critical data and programs regularly.
• Watch out for unexpected changes in file size.
• Use password protection to limit access to your system or network.

**Erased Files**
Erasing a file from a diskette or hard disk does not destroy the file. With the right software, all or part of an erased file can be reclaimed. This can be a security risk if you sell or give someone a system that once contained classified or confidential information.

To help ensure that no readable information is left on a hard disk, you can do a low-level format. An operating-system format operation does not remove all information from a hard disk.

The operating-system format operation works a little differently with diskettes. It writes a repeated pattern over the entire surface. Any information that was on the diskette becomes unreadable.

Depending on the type of information stored, your company might require additional safeguards.

**Backup Power Supply**
To prevent the loss of data caused by a power fluctuation, you can install a backup power supply. The two basic types of commercially available backup power supplies are **uninterruptible** and **standby**.

**Uninterruptible Power Supply:** This type of power supply works as an interface between the main power source and the server. It automatically takes over when the main power source is lost.

An uninterruptible power supply connects directly to the main power source (electrical outlet). The server then connects to the
power supply. The power supply transfers the power from the main power source to its internal battery, which then provides the power to the server.

Uninterruptible power supplies require no switching time (because they are always on), and they protect the server from power surges. However, they usually cost more than standby power supplies.

*Standby Power Supply:* This type of power supply waits until it detects a drop in voltage, then switches on and provides power to the server until its battery power is depleted. A standby power supply is usually less expensive than an uninterruptible power supply. A disadvantage of a standby power supply is the amount of time that it needs to switch itself on; the more time it takes, the greater the chance of losing data.
Appendix A. Product Warranties and Notices

Warranties
The following is the statement of limited warranty for the United States, Canada, and Puerto Rico.

International Business Machines Corporation Armonk, New York, 10504

Statement of Limited Warranty
The warranties provided by IBM in this Statement of Limited Warranty apply only to Machines you originally purchase for your use, and not for resale, from IBM or your reseller. The term “Machine” means an IBM machine, its features, conversions, upgrades, elements, or accessories, or any combination of them. Unless IBM specifies otherwise, the following warranties apply only in the country where you acquire the Machine. If you have any questions, contact IBM or your reseller.

*Contact your place of purchase for warranty service information.

Production Status
Each Machine is manufactured from new parts, or new and used parts. In some cases, the Machine may not be new and may have been previously installed. Regardless of the Machine's production status, IBM's warranty terms apply.

The IBM Warranty for Machines
IBM warrants that each Machine 1) is free from defects in materials and workmanship and 2) conforms to IBM's Official Published Specifications. The warranty period for a Machine is a specified, fixed period commencing on its Date of Installation. The date on your receipt is the Date of Installation, unless IBM or your reseller informs you otherwise.

During the warranty period IBM or your reseller, if authorized by IBM, will provide warranty service under the type of service designated for the Machine and will manage and install engineering changes that apply to the Machine.

For IBM or your reseller to provide warranty service for a feature, conversion, or upgrade, IBM or your reseller may require that the Machine on which it is installed be 1) for certain Machines, the designated, serial-numbered Machine and 2) at an engineering-change level compatible with the feature, conversion, or upgrade. Many of these transactions involve the removal of parts and their return to IBM. You represent that all removed parts are genuine and unaltered. A part that replaces a removed part will assume the warranty service status of the replaced part.

If a Machine does not function as warranted during the warranty period, IBM or your reseller will repair it or replace it with one that is at least functionally...
equivalent, without charge. The replacement may not be new, but will be in good working order. If IBM or your reseller is unable to repair or replace the Machine, you may return it to your place of purchase and your money will be refunded.

If you transfer a Machine to another user, warranty service is available to that user for the remainder of the warranty period. You should give your proof of purchase and this Statement to that user. However, for Machines which have a life-time warranty, this warranty is not transferable.

**Warranty Service**

To obtain warranty service for the Machine, you should contact your reseller or call IBM. In the United States, call IBM at 1-800-772-2227. In Canada, call IBM at 1-800-565-3344. You may be required to present proof of purchase.

IBM or your reseller will provide certain types of repair and exchange service, either at your location or at IBM's or your reseller's service center, to restore a Machine to good working order.

When a type of service involves the exchange of a Machine or part, the item IBM or your reseller replaces becomes its property and the replacement becomes yours. You represent that all removed items are genuine and unaltered. The replacement may not be new, but will be in good working order and at least functionally equivalent to the item replaced. The replacement assumes the warranty service status of the replaced item. Before IBM or your reseller exchanges a Machine or part, you agree to remove all features, parts, options, alterations, and attachments not under warranty service. You also agree to ensure that the Machine is free of any legal obligations or restrictions that prevent its exchange.

You agree to:

1. obtain authorization from the owner to have IBM or your reseller service a Machine that you do not own; and
2. where applicable, before service is provided —
   a. follow the problem determination, problem analysis, and service request procedures that IBM or your reseller provide,
   b. secure all programs, data, and funds contained in a Machine, and
   c. inform IBM or your reseller of changes in a Machine’s location.

IBM is responsible for loss of, or damage to, your Machine while it is 1) in IBM’s possession or 2) in transit in those cases where IBM is responsible for the transportation charges.

**Extent of Warranty**

IBM does not warrant uninterrupted or error-free operation of a Machine.

The warranties may be voided by misuse, accident, modification, unsuitable physical or operating environment, improper maintenance by you, removal or alteration of Machine or parts identification labels, or failure caused by a product for which IBM is not responsible.
THESE WARRANTIES REPLACE ALL OTHER WARRANTIES OR CONDITIONS, EXPRESS OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OR CONDITIONS OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE. THESE WARRANTIES GIVE YOU SPECIFIC LEGAL RIGHTS AND YOU MAY ALSO HAVE OTHER RIGHTS WHICH VARY FROM JURISDICTION TO JURISDICTION. SOME JURISDICTIONS DO NOT ALLOW THE EXCLUSION OR LIMITATION OF EXPRESS OR IMPLIED WARRANTIES, SO THE ABOVE EXCLUSION OR LIMITATION MAY NOT APPLY TO YOU. IN THAT EVENT SUCH WARRANTIES ARE LIMITED IN DURATION TO THE WARRANTY PERIOD. NO WARRANTIES APPLY AFTER THAT PERIOD.

**Limitation of Liability**

Circumstances may arise where, because of a default on IBM’s part or other liability you are entitled to recover damages from IBM. In each such instance, regardless of the basis on which you are entitled to claim damages from IBM (including fundamental breach, negligence, misrepresentation, or other contract or tort claim), IBM is liable only for:

1. damages for bodily injury (including death) and damage to real property and tangible personal property; and
2. the amount of any other actual direct damages or loss, up to the greater of U.S. $100,000 or the charges (if recurring, 12 months’ charges apply) for the Machine that is the subject of the claim.

UNDER NO CIRCUMSTANCES IS IBM LIABLE FOR ANY OF THE FOLLOWING: 1) THIRD-PARTY CLAIMS AGAINST YOU FOR LOSSES OR DAMAGES (OTHER THAN THOSE UNDER THE FIRST ITEM LISTED ABOVE); 2) LOSS OF, OR DAMAGE TO, YOUR RECORDS OR DATA; OR 3) SPECIAL, INCIDENTAL, OR INDIRECT DAMAGES OR FOR ANY ECONOMIC CONSEQUENTIAL DAMAGES (INCLUDING LOST PROFITS OR SAVINGS), EVEN IF IBM OR YOUR RESELLER IS INFORMED OF THEIR POSSIBILITY. SOME JURISDICTIONS DO NOT ALLOW THE EXCLUSION OR LIMITATION OF INCIDENTAL OR CONSEQUENTIAL DAMAGES, SO THE ABOVE EXCLUSION OR LIMITATION MAY NOT APPLY TO YOU.
